## Abstract

1. Connectivity loss during habitat fragmentation poses a serious threat to global biodiversity. The effects of this process depend on factors such as the dispersal ability and breeding systems of each species, the type of land use surrounding the habitat remnants and the position of fragments in the landscape.
2. Termites are abundant in tropical ecosystems, and within this group, soil-feeding species are the most sensitive to environmental degradation.
3. We investigated whether the fragmentation of the Atlantic Forest that occurred approximately 110 years ago because of sugarcane plantations in Northeast Brazil affected the genetic diversity of a population of *Embiratermes neotenicus* (Termitidae: Syntermitinae) in 14 fragments separated by 3 m to 104 m over an extent of 20 km.
4. For 10 nests in each fragment, 10 individuals ( $n = 1400$ ) were genotyped at five microsatellite loci. Our results show that the population exhibits weak genetic structure, with no relations between genetic variability and fragment features.
5. This result may be explained by the extraordinarily long lifespan of individual colonies, given this species' peculiar breeding system, offering several opportunities for dispersal events and patch colonization.
6. Landscape features such as the arrangement of forest fragments and seasonal nature of the sugarcane matrix could enable this species to maximize dispersal success and avoid local extinction.

**Keywords:** connectivity; isolation; microsatellites; population genetic structure; termites.

## Introduction

Habitat fragmentation poses a serious threat to biodiversity and ecological processes in ecosystems worldwide (Fletcher et al. 2018; Haddad et al. 2015). This process decreases the size of populations and limits dispersal. Consequences include a reduction in gene flow, the loss of genetic variability and adaptive potential, and inbreeding depression (Fahrig 2001; Keyghobadi 2007). However, the magnitude of fragmentation effects depends on several factors such as the dispersal ability and breeding system of each species (Fahrig 2001; Fougereyrollas et al. 2018), the type of land use surrounding the habitat remnants (Debinski 2006; Jules & Shahani 2009; Ricketts 2001) and the position of fragments in the landscape (Sauders, Hobbs & Margules 1991).

Tropical rainforests are the biome that has suffered the most from environmental fragmentation (Taubert et al. 2018). Among such rainforests, the Atlantic Forest stands out as one of the largest on the planet, originally covering 148.194.638 ha and occupying most of the Brazilian coast, northeastern Argentina and northeastern Paraguay (Carlson, Mitchell & Rodriguez 2011; Izquierdo, De Angelo & Aide 2008; Ribeiro et al. 2009). It harbors 1 to 8% of the world's biodiversity and is one of the most important hotspots for biodiversity conservation (Marchese 2015; Silva & Casteleti 2005). It is also one of the most degraded ecosystems, with only 11.4 to 16% of its original surface remaining, and is subdivided into thousands of fragments, mainly because of the expansion of agricultural frontiers and urbanization (Joly, Metzger & Tabarelli 2014; Reis et al. 2002; Ribeiro et al. 2009).

Termites (Blattodea: Isoptera) are abundant in humid tropical ecosystems, such as the Atlantic Forest, and are key players in nutrient cycling and energy flow (Dangerfield, McCarthy & Ellery 1998; Vasconcellos 2010). Soil-feeding termites are particularly numerous and diversified in humid forests, where they contribute significantly to soil

humification (Martius 1994; Vasconcellos 2010). Soil-feeding termites are also the most sensitive types of termites to environmental changes, presenting the potential to be used as model organisms for fragmentation studies (Davies 2002; Dupont et al. 2009).

Among soil-feeding species, *Embiratermes neotenicus* (Holmgren, 1906) is widely distributed and abundant in rainforests and has been frequently recorded in the Atlantic Forest (Cancello et al. 2014; Ernesto et al. 2014; Souza, Alves & Vasconcellos 2012). This species constructs well-defined epigeal nests, and colonies are initiated by a pair of primary reproductives (king and queen). The dispersal and mating strategies include long-distance flights resulting in outbreeding (Fougeyrollas et al. 2018). Therefore, we selected *E. neotenicus* as a suitable model to study the effect of environmental fragmentation. In the present study, we investigated whether the fragmentation of the Atlantic Forest that occurred approximately 110 years ago because of sugarcane plantations in Northeast Brazil impacted the genetic variability and genetic structure of a population of *E. neotenicus* in 14 fragments. For 10 nests in each fragment, 10 individuals ( $n = 1400$ ) were genotyped at five microsatellite loci. Considering that the type of matrix that surrounds a fragment can affect the isolation of populations (i.e., during dispersal events), we tested whether the distance between fragments impacts gene flow and whether genetic diversity correlates with the size, shape or forest cover around the fragments.

## **Material and methods**

### **Study area and biological material**

Collections of *E. neotenicus* were carried out between May 2016 and June 2017 in 14 forest fragments located at Usina São José, Igarassu, Pernambuco (S7°49'07" and W35°00'45"), in the northern portion of the Atlantic Forest in Northeast Brazil. The climate is hot and humid. The average annual temperature is 26.3 °C, the relative air humidity is 83.9%, and the average monthly rainfall is 121.3 mm (data collected at the meteorological station of the Usina São José between January and December of 2016). The average wind speed is 18.29 km/h, predominantly in the east-southeast direction (Weatherspark 2018). The soil originates from sediments of the Barreira Group and is classified as a deep sandstone clay ranging from sandy to clayey clay with low to medium fertility. The relief varies from flat to smooth undulating, and the original vegetation is classified as subperenifolia forest (Koffler et al. 1986). Sugarcane was planted in 1906 (Gaspar 2009) and currently has a total planting area of 280 km<sup>2</sup> and isolates 110 Atlantic Forest fragments with different sizes and shapes (Silva et al. 2012), 14 of which were selected for this study (Fig. 1). The fragments were located 3 m to 104 m from other fragments over an extent of 20 km. For each fragment, the total area, shape (i.e. the ratio between the perimeter of the fragment and the minimum perimeter of the fragment in terms of the number of cell surfaces (Bogaert et al. 2000; Milne 1991)) and forest cover within a radius of 1 km around the fragments were measured (Table 1). The values of these attributes were obtained by accessing data from the Geographic Information System (GIS) developed for the study area by Trindade et al. (2008) using multispectral satellite images. In each of the 14 fragments, workers and soldiers from 10 nests of *E. neotenicus* were collected and stored in absolute ethanol ( $n = 140$  nests in total).

### **DNA extraction, amplification and genotyping**

Total genomic DNA was extracted from the head of five soldiers and five workers from each of the sampled nests, totaling 1400 samples. Extraction was performed using a Chelex-based method (Walsh, Metzger & Higuchi 1991). Individuals were genotyped at 5 microsatellite loci with dinucleotide repeat motifs (En-08, En-10, En-11, En-15 and En-19) previously used to investigate the colony genetic structure in a population of *E. neotenicus* from French Guiana (Fougeyrollas et al. 2015).

DNA amplification was performed in two PCR multiplexes, each with a total volume of 25  $\mu$ L and containing 0.2  $\mu$ L (1 U) of FastStart Taq DNA Polymerase (Roche Diagnostics), 2.5  $\mu$ L of 10X PCR buffer, 1.5  $\mu$ L of 25 mM  $MgCl_2$ , 0.6  $\mu$ L of 10 mM dNTP mix, 0.2  $\mu$ M each forward and reverse primer (En-08 and En-10 in multiplex 1; En-11, En-15 and En-19 in multiplex 2; Table S1), 2  $\mu$ L of template DNA and PCR-grade water (q.s.).

The following cycling conditions were used: an initial denaturing step at 95°C for 10 min; 40 cycles of denaturation at 95°C for 30 s, annealing at 60°C for 30 s, and extension at 72°C for 60 s; and a final extension step at 72°C for 10 min. Amplicons were visualized on an ABI 3730XL sequencer (Applied Biosystems). Fragment lengths were manually checked on chromatograms, and genotypes were scored using Peak Scanner v1.0 software (Applied Biosystems).

## **Statistical analyses**

### **Microsatellite characteristics**

We investigated microsatellite marker characteristics in the population by randomly choosing one individual per nest ( $n = 140$ ; Supporting Table S2) and checking for the presence of null alleles or scoring errors owing to large allelic dropout using Micro-Checker v2.2.3 software

(Van Oosterhout et al. 2004). Deviations from Hardy-Weinberg equilibrium were tested using GENEPOP 4.2 (<http://genepop.curtin.edu.au>; Raymond & Rousset 1995; Rousset 2008).

### **Genetic structure of colonies**

We evaluated colony breeding systems by calculating the number of alleles and genotypes at each locus across all genotyped individuals ( $n = 1400$ ; Supporting Table S2). Furthermore, average within-colony relatedness ( $r_{nest}$ ) *sensu* Queller & Goodnight (1989) was calculated using the “grouprel” function in the R package 'related' v1.0 (Pew et al. 2015), and within-colony inbreeding coefficients ( $F_{IC}$ ; Weir & Cockerham 1984) were computed using GENEPOP4.2.

### **Genetic diversity analyses**

The genetic diversity in each investigated fragment of the Atlantic Forest was assessed by randomly choosing one individual per nest ( $n = 140$ ), the same dataset used to investigate the microsatellite characteristics. We calculated the number of alleles, the observed and expected heterozygosities and the fixation index using GenAlEx 6.5 software (Peakall & Smouse 2012). These parameters of genetic diversity were compared between fragments using one-way analysis of variance (ANOVA) with R software v3.5.3 (R Core Team 2018).

The relations between landscape features and genetic diversity were tested using generalized linear models, adopting a Gaussian family distribution (Dobson 1990). Two models were created. The first model included the number of alleles as the response variable and landscape features as explanatory variables, and the second model included observed

heterozygosity as the response variable and landscape features as explanatory variables. The models were run in R v3.5.3.

### **Population genetic structure and landscape genetic analyses**

Population genetic structure and landscape genetic analyses were performed by randomly choosing one individual per nest ( $n = 140$ ), the same dataset used to investigate the microsatellite characteristics and genetic diversity analyses. The relationship between geographic and genetic distances was assessed using a Mantel test with 9999 permutations, and the pairwise  $F_{ST}$  and the relative probability were calculated using GenAlEx 6.5 (Peakall & Smouse 2012). Population genetic structure was estimated with a Bayesian model-based clustering method. The number of population clusters ( $K$ ) was obtained using STRUCTURE v2.3.4 software (Pritchard, Stephens & Donnelly 2000) under an admixture model with correlated allelic frequencies among populations. Simulations were run 20 times for  $K=1-14$  with a burn-in of 50000 and 100000 Markov chain Monte Carlo (MCMC) repetitions. The optimal  $K$  value was determined with STRUCTURE HARVESTER v0.6.94 (Earl & vonHoldt 2012) using the delta  $K$  method (Evanno, Regnaut & Goudet 2005). CLUMPP v1.1.2 (Jakobsson & Rosenberg 2007) was used to align simulations for the optimal  $K$  and eliminate label switching among clusters using the *Greedy* algorithm with 200000 replicates. Graphical results were obtained using DISTRUCT v1.1 (Rosenberg 2003). Genetic structure was also tested by calculating the genetic divergence between populations ( $F_{ST}$ ), and hierarchical  $F$ -statistics were estimated at different levels, specifically, the degree of inbreeding among nestmates ( $F_{IC}$ ) and differentiation between colonies within the population of fragment ( $F_{CP}$ ), using the R package 'hierfstat' (Goudet 2005).

To test the effect of landscape features on population genetic structure, site-specific

genetic differentiation (population-specific  $F_{ST}$  value) was estimated and related to landscape features using generalized linear models by applying a hierarchical Bayesian method in GESTE 2.0 software (Foll & Gaggiotti 2006). We used the reversible jump MCMC method and 10 pilot runs with a length of 5000 as a burn-in prior to drawing samples from a chain with a length of 50000, separated by a thinning interval of 20. We ran seven models with a single landscape variable or combination of the landscape variables: size; shape; forest cover; size and shape; size and forest cover; shape and forest cover; and size, shape and forest cover.

## **Results**

### **Microsatellite characteristics**

No sign of null alleles was detected at the population level except at locus En-10 (frequency of 0.29), as suggested by the general excess of homozygotes. There was no evidence of scoring error due to large allele dropout. Therefore, the locus En-10 was not included in subsequent analyses.

All microsatellite loci were polymorphic. The number of alleles per locus varied from 3 (En-19) to 23 (En-11). The loci En-08 and En-11 showed significant deviation from Hardy-Weinberg equilibrium ( $P < 0.05$ ). The microsatellite characteristics are summarized in Supporting Table S1.

### **Genetic structure of colonies**

The genotypes of the individuals are presented in Supporting Table S2. All genotyped individuals were heterozygous for at least one marker (Table S3). Most of the colonies (70%; 98 nests) were compatible with a simple family design, i.e., individuals were derived from a single pair of primary reproductives and displayed a maximum of four alleles and genotypes

at a given locus. However, 40 colonies (28.5%) exhibited a maximum of four alleles but more than four different genotypes, which is consistent with an extended family design. The remaining two colonies presented more than four alleles, therefore being consistent with a mixed family design. The within-colony pairwise relatedness ( $r_{nest}$ ; mean  $\pm$  sd:  $-0.260 \pm 0.170$ ) and inbreeding coefficients ( $F_{IC}$ ; mean  $\pm$  sd:  $-0.262 \pm 0.169$ ) within colonies are shown in Table S3.

### **Genetic diversity analyses**

Over the four retained loci, the mean number of alleles per fragment ranged from 4 to 6 (Table 2). The fragments with the largest number of private alleles were VV and ZB (two alleles). Across all investigated sites, En-11 presented the largest number of private alleles (five alleles; Table S4). The observed heterozygosity ranged from 0.40 to 0.70, the expected heterozygosity ranged from 0.46 to 0.58, and the fixation index ranged from -0.22 to 0.11 (Table 2). Genetic diversity did not differ among fragments: there was no difference in the number of alleles ( $F_{13,42} = 0.113$ ;  $P > 0.05$ ), observed heterozygosity ( $F_{13,42} = 0.258$ ;  $P > 0.05$ ) or expected heterozygosity ( $F_{13,42} = 0.108$ ;  $P > 0.05$ ). Moreover, there was no difference between expected heterozygosity and observed heterozygosity ( $F_{1,26} = 0.151$ ;  $P > 0.05$ ).

### **Population genetic structure and landscape genetic analyses**

No significant correlation was found between genetic differentiation and geographical distance (Mantel test:  $r = 0.0186$ ,  $P = 0.196$ ; Fig. S1). The pairwise  $F_{ST}$  between fragments and the relative probability are presented in Supplementary Table S5.

STRUCTURE analysis revealed that  $K = 7$  was the optimal number of genetic clusters. No differentiation of the genetic profiles was observed among the sampled

populations, and the seven clusters were represented in all individuals at similar proportions (Fig. S2). The populations exhibited moderate genetic structure ( $F_{ST} = 0.076$ ), while the pairwise  $F_{ST}$  between fragments (Table S5) indicated low to moderate genetic structure according to the classification of Wright (1978). Accordingly, hierarchical  $F$ -statistics showed differentiation between colonies within the same site ( $F_{Nest/Site} = 0.519$ ), while sites did not differ from each other for the investigated population ( $F_{Site/Pop} = 0.027$ ). There were no relations between landscape features and either genetic diversity (Table 3) or population genetic structure (the models including only the constant showed the highest probability for all combinations of landscape features; Table 4).

## Discussion

Our results revealed moderate genetic structuring of *E. neotenicus* among the 14 Atlantic Forest fragments investigated, indicating that gene flow probably occurs between them or that the fragments have not been isolated long enough to promote genetic differentiation.

Flying high is an important feature of dispersal for tropical rainforest termites. Although alates of ground-dwelling species spend more time in lower strata than in upper strata, some species can fly at a height up to 28 m, such as *Embiratermes chagresi* (Bourguignon et al. 2009). Flying above the canopy would allow the termites to take advantage of winds and maximize their dispersal. In fact, the seasonal nature of sugarcane cultivation exposes the surrounding forest fragments to increased wind action in the postharvest period (Ferrante et al. 2017). In the northeastern part of Brazil, the sugarcane harvest occurs mainly between September and March, while the vast majority of the species belonging to the Termitidae in the Atlantic Forest swarm between March and May (Medeiros, Bandeira & Martius 1999), as is also the case for *E. neotenicus* in our study sites (pers. obs.).

Thus, during the swarming period, the matrix consists of uncovered soil or small and young plants, which could facilitate the dispersal of alates among forest remnants by wind action. In addition, the preharvest practice of burning sugarcane is still commonly applied and leads population declines of natural predators of termites such as small mammals (Griffiths & Brook 2014) and arthropods such as ants (Vasconcelos et al. 2009). Therefore, swarming shortly after harvest would allow winged reproductives to achieve higher dispersal success.

Long-distance dispersal increases local genetic diversity and decreases levels of population differentiation, effectively avoiding the effects of fragmentation. Other studies support the idea that termites are able to disperse over long distances (Mona et al. 2013). The population genetic structure of *Nasutitermes takasagoensis* (Termitidae: Nasutitermitinae) was investigated among oceanic islands separated by 200 m to 443 km. Populations presented moderate genetic structure when separated by a distance up to 46 km, indicating the occurrence of gene flow (Garcia et al. 2002; García et al. 2004). García et al. (2006) studied the genetic diversity of *Nasutitermes coxipoensis* in Cerrado fragments in Brazil and observed no restriction to gene flow and no genetic differentiation between fragments separated by less than 60 km, which may be partly explained by the seasonal production and release of thousands of alates by each nest.

The dispersal and mating strategies of *E. neotenicus* were studied in a connected rainforest of French Guiana (Fougeyrollas et al. 2018). The results suggest that long-distance flights are the rule for this species, leading to no or low genetic differentiation between study sites separated by up to 10 km. In a population in French Guiana, colonies of *E. neotenicus* were determined to be simple families and were shown to undergo asexual queen succession (AQS; Fougeyrollas et al. 2015, 2018). In this breeding system, nondispersing (neotenic) queens are parthenogenetically produced, while workers, soldiers and alates are produced

sexually by mating between the primary king and the primary queen or neotenic queens. In *E. neotenicus*, the primary queen is replaced by multiple neotenic queens (up to almost 200) early in the colony's life cycle (Fougeyrollas et al. 2015). As these neotenic queens are parthenogenetically produced, their matings with the primary king do not change the colony's genetic structure, and no inbreeding occurs. The AQS breeding system was also described in other soil-feeding termites at the same study site in French Guiana: *Silvestritermes minutus* (Termitidae: Syntermitinae) and several species belonging to the *Termes* group (Termitidae: Termitinae) (Fougeyrollas et al. 2017; Fournier et al. 2016; Hellemans et al. 2019). As in *E. neotenicus*, most colonies of *S. minutus* and *Cavitermes tuberosus* were founded by unrelated reproductives as a result of long-distance dispersal, and no population genetic structure was observed (Fougeyrollas et al. 2018; Fournier et al. 2016).

The main advantages of AQS appear to be the expansion of colony reproductive potential through the reproduction of many more queens and an increase in lifespan via the ability of replacement queens to produce subsequent generations of parthenogens (Matsuura 2017). Therefore, through an enhanced lifespan, colonies have several opportunities to produce alates. It follows that such mechanisms may contribute to maximizing the odds of colonizing a neighboring patch over the years and maintaining gene flow between the investigated Atlantic Forest fragments.

Our study suggests that gene flow prevents genetic differentiation between the fragments investigated, resulting in a small number of private alleles between fragments and no relationships between genetic diversity and fragment features. The same observation was made in other studies on invertebrate populations with low genetic structure in fragmented habitats (Garcia et al. 2006; Ramirez & Haakonsen 1999). Therefore, depending on the circumstances, a fragmentation event will not necessarily lead to a loss of genetic diversity

(Young, Boyle & Brown 1996). Our work demonstrates that agricultural practices can be maintained in a landscape context where the deleterious effects of natural habitat loss are mitigated by the functional connectivity of forest fragments. In the context of the landscape studied here, the proximity of fragments acts in synergy with the dispersal capacity of *E. neotenicus* and favors gene flow between the populations, and such a landscape context may also be favorable for other insects providing ecosystem services.

595

596 **Table S2.** Genotypes of individuals of *E. neotenicus* from 14 Atlantic Forest fragments in  
597 Northeast Brazil (Pop – population; Ind – individual). Samples in bold correspond to  
598 randomly choosing one individual per nest used to access the microsatellite characteristics,  
599 Genetic diversity analyses, population genetic structure and landscape genetic analyses.

**Fig. 1.** A – Location of the study area. Dark gray - Atlantic Forest; B - Atlantic Forest fragments of the Usina São José, Igarassu, Pernambuco, Brazil. Light gray - Atlantic Forest fragments sampled.

**Fig. S1.** Relation between pairwise  $F_{ST}$  and geographical distance (km) for *E. neotenicus* populations from 14 fragments of the Atlantic Forest in Northeast Brazil.

**Fig. S2.** Genetic structure analysis of *E. neotenicus* populations from 14 fragments of the Atlantic Forest in Northeast Brazil based on one individual per colony and four microsatellite loci. A - The most likely  $K$  value corresponds to the uppermost hierarchical level among runs. B - Population genetic structure as inferred using the Bayesian clustering algorithm in STRUCTURE for  $K=7$ . The colored segments represent the proportion of each genetic cluster. The identification of populations is indicated above.
